ABSTRACT

A magnetorheological is a new generation of smart materials in active mechanical vibration and shock control applications. This article is based on a comparative experimental study of the dynamic properties of magnetorheological elastomers (MRE) and magnetorheological fluids (MRF), whose damping and stiffness are controlled simultaneously by applying magnetic field intensity. The dynamic visco-analyser and rheometer were used to test the behaviour of MRE and MRF. The response of both materials depends on the amplitude due to shear strain. The experimental results clearly show the difference between the dynamic properties of MRE and MRF. More specifically, MFRs have high damping with low stiffness; on the other hand, the MRE has average damping with outstanding rigidity. These results help designers achieve more efficient and reliable structures in various engineering fields, such as buildings and mechanical applications.

1. INTRODUCTION

Innovative materials such as magnetorheological fluids (MRF) and magnetorheological elastomers (MRE) have become preferred materials in many applications due to the ability to change properties in a controlled manner under the application of stimulation such as variable current, magnetisation, heat, force, stress, and strain. In addition, the magnetic field controls the physical change of the mixture to the semi-solid state, making these materials a reliable element in active vibration and mechanical shock control applications.

In recent years, worm-like micelles (WLMs) have been used by Ghatee et al. [1] to improve the properties of water-based MRFs. Cetyl trimethyl ammonium bromide
(CTAB) was used as a dispersant in the study. Lamprecht et al. [2] evaluated a hydrostatic bearing in which the pressure profile of a conventional hydrostatic bearing is recreated with only the use of a magnetic field and a magnetorheological fluid. Jian-Feng et al. [3] studied a magnetorheological liquid to recycle the oil slick efficiently. A core-shell material of magnetic nanoparticles (MPs) of Fe3O4 coated with oleic acid (OA) was uniformly dispersed in a base fluid.

Vishnyakov et al. [4] have developed a new independent description of flows in plastic and viscous regions that could be used to study magnetohydrodynamic flows of Bingham fluid. The design of an MR damper, consisting of piston and cylinder arrangement, was presented by Mangal et al. [5]. Xufeng et al. [6] used a DC Arc discharge method to prepare iron nanoparticles. The morphology, magnetic properties, crystal structures and surfaces chemical composition were examined. Sahoo et al. [7] have shown that the values of dynamic yield stress corresponding to different applied magnetic field intensities increase with increasing magnetic field intensity. Pant et al. [8] studied the effect of ferrofluid incorporated (5–20% v/v) flake-shaped iron particles in silicon oil-based magnetorheological fluid (MR fluid).

In the work of Zhong-jin et al. [9], numerical analysis on magnetorheological elastomers bulging for sheet metal was carried out. The obtained results indicated that the shear modulus of the magnetorheological elastomer increases with the increase of the magnetic intensities. Tong et al. [10] prepared Flower-like Cobalt Particle-Based MRE (FCP-MRE), Spherical Cobalt Particle-Based MRE (SCP-MRE), and Flower-like MRE Coupling Agent modified cobalt (M-SCP-MRE) for comparison. With recent advances in X-ray microtomography, allowing the mutual evaluation of large particles, the PCF could be applied to tomographically captured three-dimensional particle structures [11].

An external stimulus activates MREs, an appropriate candidate for 4D printing where a shape-shifting of a 3D printed structure under external stimuli over time was needed [12][13]. Michal et al. [14] have developed a composite material based on a geopolymer matrix and a reinforcement of basalt fibres. Bodnaruk et al. [15] have shown that the constant magnetic anisotropy resulted from particle displacements and a characteristic of the energy of internal deformations in the polymer matrix.

Aigirre-Olabide et al. [16] have developed a new magneto-viscoelastic model for anisotropic magnetorheological elastomers (MREs), combining dynamic behaviour and magnetic permeability components. Zuzana et al. [17] have studied the effects of the reinforcement phase in particular ceramic composites on their properties. Nedjar and al. [18] determined the mechanical characteristics of a magnetorheological elastomer loaded with 20, 30 and 40% iron particles.

The effect of temperature on the dynamic mechanical properties of MR elastomers has been examined by Wan et al. [19]. The impact of the nature of the particles on the mechanical properties and the magnetic effect of elastomers MRE have been studied by Kumar et al. [20]. Wang et al. [21] have developed nanocomposites of cobalt ferrite (CoFe2O4) nanoparticles grown on multi-walled carbon nanotubes (MWCNT) by the ultrasound-assisted coprecipitation technique. Kumar et al. [22] used two magnetisable particles (carbonyl iron (Ci) and electrolytic iron (El)). These two particles were collected and characterised using an Anton Paar MCR 702 rheometer setup in on and off states. Niu et al. [23] discussed a study of the dynamic analysis and vibration control of the boring bar system with magnetorheological fluid control. In this article, Zhang et al. [24] performed a numerical study on domed magnetorheological elastomers for sheet metal. The speed and stress distribution of the sheet under different magnetic intensities were compared and analysed. Jambiz et al. [25] experimentally and numerically studied the magmoto-hyper-viscoelastic responses of isotropic magnetorheological elastomers (MREs) subjected to uniaxial compressive loads and induced by magnetic fields.

This article, a comparative study between magnetorheological elastomers and magnetorheological fluids, aims to help engineers exploit these recent materials in different fields of application by identifying their dynamic properties as a function of the shear strain amplitude experimentally.

2. ANALYTICAL MODELING

A micromechanical analytical model has been developed on an elementary cell that can generate a representative chain by replicating along the chain’s axis to describe the behaviour of the magnetorheological elastomer composite. This cell is a cylinder, a real agglomerate of the composite; it consists of two hemispheres coated in a large cylinder of elastomer. In reality, the magnetorheological composite has a very complex microstructure; one can think of aggregates disturbing the arrangement of chains, misalignment and length of chains. There are columnar aggregates formed of several particle thicknesses. The finest area could be observed by electron microscope, and the area separating the particles increases.

The approach adopted is to isolate the essential physical parameters for this type of system: the anisotropic structure, the gap separating two particles within the same chain, and the volume fraction of the charges. Thus, the
overall design is made of particles ideally spaced by the same gap, making the ratio of the gap over the radius of the particles the essential parameter of this model. The volume fraction $\phi$ fixes the inter-chain distance, represented here by the quantity $L$. $L$ is the thickness of the elastomer ring surrounding the particles and is calculated as a function of the ratio $g/a$ and of the volume fraction $\phi$ of inclusions, given as follows:

$$\phi = \frac{V_{\text{Particles}}}{V_{\text{Matrix}} + V_{\text{Particles}}} \tag{1}$$

In the study, experiments were conducted to characterise the dynamic properties of the MRE over the strain amplitude, magnetic flux density. The loss angle was determined by:

$$\delta = \frac{G''}{G'} \tag{2}$$

Where:

$$G' = G^* \cos(\delta) \tag{3}$$

$$G'' = G^* \sin(\delta) \tag{4}$$

The complex modulus $(G)$ is the ratio of the shear stress $\tau(t)$ and shear strain $\gamma(t)$, given as follows:

$$\phi = \frac{\tau}{\gamma} \tag{5}$$

Therefore, the loss modulus could be estimated from the energy dissipation, corresponding to the hysteresis loop area [26]. Thus, the energy dissipation $D$ per loading cycle is expressed as:

$$D = \int_0^T \tau(t) \gamma(t) dt = \pi \gamma_d^2 G^* \sin(\delta) = \pi \gamma_d^2 G'' \tag{6}$$

3. MATERIALS AND METHOD

3.1. Magneto rheological fluid

MRF is a smart material that reacts almost instantly to an applied magnetic field by changing its rheological properties. MRF is one of the categories of fluids sensitive to the application of a magnetic field. It consists of ferromagnetic particles (spherical or elliptical in shape) of the order of a micrometre from 0.1 to 10 $\mu m$ bathed in a carrier liquid, also called a solvent. A variety of carrier fluids could be found, most organic, such as mineral oil. It is large enough particles to accommodate multiple magnetisable domains (Weiss domains).

In the absence of a magnetic field, the spin orientations relating to each part were randomly arranged. Thus, the resulting magnetisation at the particle level was zero. There was, therefore, no magnetic interaction force between two or more ferromagnetic suspensions.

Consequently, the metal particles were homogeneously dispersed within the carrier liquid: the resulting viscosity is then very low but constant during shearing.

On the other hand, when this fluid was subjected to an external magnetic field of the order of a Tesla fraction, the spin moments tend to orient themselves in the same direction as the field (by minimisation of the interaction energy). There then appeared a magnetic interaction force was joining between particles. The apparent viscosity $\eta$ of the fluid increased very sharply, so much so that it behaved like a viscoelastic solid. The ferromagnetic particles then lined up in the same direction as the magnetic field lines and formed actual chain structures.

3.2. Magnetic device for MRF

Figure 1 shows the Couette-plan rheometer. In experiments, a sample of magnetic fluid was placed in the air gap to occupy all the available space. Note that the field was saturated because an iron core drives it. As air bubbles in the fluid were a source of error, it must be careful to burst them. The rheometer imposed increased stress in the air gap, then the acquisition software attached to the rheometer calculated the speed at which the magnetic fluid shifts.

![Figure 1. Couette-plan rheometer.](image)

3.3. Magneto rheological elastomer

A Dynamic Mechanical Analyser (DMA) machine was used to perform dynamic tests on small samples by varying the frequency. The objective was to investigate the role of microstructure on the macroscopic response of the elastomer composite when having the magneto-mechanical loading conditions. The dynamic mechanical analysis (MetraVib DMA +450) was applied to determine the rheological properties of MRE. The MetraVib DMA +450 consists of a very rigid frame and a movable punch, as in Figure 2.

4. RESULTS AND DISCUSSION

Experiments have been conducted on the dynamic properties of magnetorheological elastomers (MRE) and magnetorheological fluids (MRF). The key results and findings are discussed as follows.

Experimental data of MR fluid and MR elastomer with a volume fraction of 30% under an applied magnetic field of 400mT are given in Table 1 and Table 2.

Table 1. Experimental data of MR elastomer with volume fraction of 30% under applied magnetic field 400mT.

Figure 3 shows the optical micrograph of magnetic response (MR) fluids with a magnification factor of 500x. The magnetic particles are dispersed in a carrier fluid.

Figure 3. Section of the structured composite magnetorheological fluid observed by optical microscope.

A microscope could observe the finest area, and the area separating the particles increases Figure 4.

Figure 4. Section of the structured composite magnetorheological elastomer observed by optical microscope.

The results of dynamic tests under a magnetic field with an intensity of 400mT are presented in Figures 5, 6 and 7.

Figure 5 indicates the variation of the storage modulus according to the shear strain energy. The storage modulus decreases as a function of the increase in the shear strain energy. The increase in rigidity of the MRE causes a decrease in storage modulus. This matches the increase in magnetic force between ferromagnetic particles and the decrease in energy stored by weak sliding between iron particles [8].

On the other hand, this modulus decreases with the increase of the strain energy in shear. The yield stress of the material decreases due to the rise of the energy losses.
in the suspensions. The inter-particles solid surface friction also causes it by smoothing the surface of particles in flake shape.

![Figure 5. Variation of storage modulus as a function of shear strain energy.](image)

Figure 5. Variation of storage modulus as a function of shear strain energy.

Figure 6 gives loss modulus as a function of shear strain energy. The shear strain energy increase leads to a significant decrease in the loss modulus for the magnetorheological elastomer. This decrease in the loss modulus is more pronounced for higher shear strain energy values. A significant reduction in the loss modulus is also observed in a magnetorheological fluid. This decrease is mainly due to the increase in the sliding effect between the ferromagnetic particles and the decline in rigidity according to the increase in viscosity.

This work is devoted to a comparative study of magnetorheological materials (MRE and MRF) from a mechanical perspective. The MRE is made up of iron particles subjected to a magnetic field. Under the magnetic field effect, the particles polarise and align in the direction of the area. The spatial distribution of particles by the magnetic field is responsible for changes in the material's mechanical properties. Due to their fibrillar structure, MRE materials are more interesting than MRF materials: they are conductors even at a low particle charge ratio.

On the other hand, many application fields use MRFs for the dissipation of mechanical energy. Their ability to rapidly change their properties, depending on a magnetic field, makes these fluids an excellent way to control the static and dynamic behaviour of various mechanical devices such as shock absorbers, brakes and clutches. However, these mechanical energy dissipators are required to operate in environments subject to external disturbances, in particular vibrations.

5. CONCLUSION

The magnetorheological fluid (MRF) and the magnetorheological elastomer (MRE) are two intelligent magnetorheological materials. It has been developed from certain products which are commercialised and used in practice. From this work, it can be concluded that magnetorheological fluids (FMRFs) have an excellent variable damping property. MRE changes their stiffness in milliseconds in the presence of a magnetic field. These materials, MRF and MRE, are of great interest in realising damping variability or stiffness variability for vibration control and mechanical shock remediation in a wide range of civil (buildings) and mechanical structures (automotive).
